This worksheet within the economic analysis model is used to evaluate financing and ownership alternatives for the project under consideration. Financial analysis is distinctly different from economic analysis. With economic analysis, returns are calculated based on total cash inflows and cash outflows, assuming that all investments are cash outflows and net incomes are cash inflows. Financial analysis allows for debt financing, equity percentages, credits, depreciation and its effect on taxation, and pre-tax versus after-tax analysis. The evaluation methodology is similar except that instead of total cash flows, equity flows are considered.

Generally speaking, if the economic Return on Investment (ROI) is greater than the interest rate on borrowed funds, financial leverage will be positive and Return on Equity (ROE) will be greater than the ROI. Financial leverage will make a good project better and a bad project worse.

Using this worksheet allows a project to be put into a form typically used by business decision-makers, where depreciation and tax effects are considered, as well as borrowing ratios and interest rates. Additionally, income and expense categories can be inflated over time.

In the table above, the project "base case" is used, and further modified by a number of considerations, including: 1) a grant (credit), 2) borrowing 75 percent of the cash requirement with a ten year term at 3% interest. The ownership structure is assumed to be a Limited Liability Company, so there is no tax effect to the project (only to the project owners). That scenario is carried forward to the next table, where the distribution of LLC earnings is considered.

The Btu balance table shown above is used to track what happens to the energy contained in the biogas that is produced in the anaerobic digester. It is shown both in daily Btus and in percentage of the total. Every Btu is accounted for in some manner, including a category for "not utilized". This table is especially useful in attempting to find better efficiencies for the project. Ideally all of the energy produced would be put to some useful and income producing end.

The table shows that this project is expected to product 295.2 million Btus per day and that 95% of the energy will pass through the engine generator to product electricity. The other 5% is lost (flared) due to assumed downtime for maintenance, etc. Ideally there would be no loss at all. The engine generator is shown to have a conversion efficiency of 35% because 35% of the Btus, which pass through the generator, are converted to electricity. The other 65% is engine heat loss, but 75% of that engine heat is recoverable. It is first used to heat the incoming material to the digester (43%) and is then available for other uses. In total, 31% (26% plus 5%) of the energy available in the biogas is being lost or not utilized. If an economically viable use could be found for that energy, it would boost the financial returns of the project.

The energy necessary to heat the incoming material to the digester is calculated independently. If more heat were needed than is available by recovery from the generator, biogas would first be used for that purpose before being available for electricity production. That is a non-productive use for the biogas and should be avoided by reducing the water content of the digester feedstock, better insulation of the digester vessels, recovering more heat from the digester effluent or any other practical means.

From the standpoint of designing the project for optimum efficiency, the Btu Balance Table is a very useful source of information.

Exhibit C-17- Liquid Handling Cost Comparison

| | Cost Fac | tors | Annual | Costs |
|---|-------------------|-------------------|-----------|------------|
| _ | <u>000 gal</u> | <u>Rate</u> | Standard | With UF/RC |
| Standard Standard | | | | |
| Manure Transport Land Application | | | \$166,303 | |
| Custom Application | 0 | \$0.00 | \$0 | |
| Dairymen | 49,671 | \$2.50 | \$124,178 | |
| With UF/RO 95% Manure Transport ** Land Application | | 80008080 | | \$133,043 |
| Custom Application Dairymen | 2,241 0 | \$12.50 \$2.50 | | \$28,017 |
| UF/RO Operating | 42,586 | \$1.00 | | \$42,586 |
| Total | | | \$290,481 | \$203,647 |
| | | | \$47.82 | \$33.52 |

This table is a comparative calculation of liquid handling cost with and without option of membrane separation of dissolved nutrients. Without the UFRO alternative, digester liquid would be returned to the dairymen in the same transport trailer that manure is hauled away and then it would have to be land-applied as is currently the practice. Land application cost includes the cost of agitation, pumping and hauling if necessary. With the UFRO alternative, there is no land application cost, other than pumping of the accumulated rainwater. With UFRO, there is an additional cost for operation of the system and for land applying the nutrient-dense liquid via spreader truck.

| | | | | | | |
| | | | | | | |

This methodology is based on AgStar program factors for potential methane emissions from various handling methods and the breakdown, by type, of handling method in the state of Washington. As shown in the right hand portion of the table, the calculation assumes that anaerobic lagoons emit 90% of the total potential methane of the waste stream, while handling manure as a liquid slurry allows only 15% of the potential methane to be emitted. The assumption is that half the waste is handled as liquid slurry and half via anaerobic lagoon. Extending the emissions by method times the percentage of each method determines overall percentage of potential methane emissions that would be allowed under standard handling practices. In this case, 52.75% of the potential methane emissions would be allowed under standard handling practices.

In the left side of the table, total potential methane emissions are calculated based on number of animals, volatile solids production per unit of body weight and chemical conversions. Potential emissions are reduced according to the standard handling practice and then multiplied by the greenhouse gas equivalency factor of methane to give the potential GHG emissions resulting from the standard manure handling practices in Washington.

This methodology does not attempt to calculate all of the details of GHG emissions as will be required for their validation trading of emissions credits. However, methane is the primary component and it can be reasoned that the additionally detailed calculations will add to the potential after the complete balance sheet is completed.
